# SUPPLEMENT TO "NATURE OR NURTURE? LEARNING AND GEOGRAPHY OF FEMALE LABOR FORCE PARTICIPATION": DATA AND ESTIMATION APPENDIX 

(Econometrica, Vol. 79, No. 4, July 2011, 1103-1138)

By Alessandra Fogli and Laura Veldkamp

Keywords: Culture, social change.

THIS APPENDIX contains details about the construction of our county-level data set, summary statistics for all variables, survey data about changing attitudes toward female labor force participation in the United States, international evidence about labor force participation, and details about the results of the dynamic panel estimation reported in Table II of the paper.

## S.1. DATA DESCRIPTION

## S.1.1. County-Level Data

Our county-level data set has information on a vast array of economic and sociodemographic variables for 3074 U.S. counties over the period 1940-2000 for each decade. Most of the information comes from Census data, in particular, from a data set called "Historical, Demographic, Economic, and Social Data: The United States, 1790-2000," ICPSR, Study 2896. However, we integrated this data set using several others, including the Census of Population and Housing, the County and City Data Book, the Census 2000 Summary Files, and IPUMS to obtain the most complete and homogeneous information at the county level for this span of time. Sources and details about the construction of each single variable are presented in Table S.I. Table S.II reports summary statistics for each variable decade by decade.

## S.1.2. Survey Data

The survey data from general social survey (GSS) begin only in 1972. However, the increasing speed of female entry into the labor force (start of the S) precedes that date. To establish the contemporaneous S-shaped evolution of beliefs, it is vital to have more historical data. We have one measure of beliefs that has been collected infrequently since the 1930s. These data are from the IPOLL data bank, maintained by the Roper Center for Public Opinion Research. Unfortunately, the phrasing of the questions differs slightly over time. We describe below the questions and the replies.

AUgust 1936: The Gallup Poll asked, "Should a married woman earn money if she has a husband capable of supporting her?" $18 \%$ said yes; $82 \%$ said no. No uncertain or no response entries were allowed.

October 1938: The Gallup Poll asked, "Do you approve of a married woman earning money in business or industry if she has a husband capable of supporting her?" $22 \%$ approve; $78 \%$ disapprove.

November 1945: The Gallup Poll (AIPO) asked, "Do you approve or disapprove of a married woman holding a job in business and industry if her husband is able to support her?" $62 \%$ disapprove; $18 \%$ approve. The rest of the replies are miscellaneous open answers (e.g., if she has a good job, if she has no children, etc.).

June 1970: The Gallup Poll asked, "Do you approve of a married woman earning money in business or industry if she has a husband capable of supporting her?" $60 \%$ approve; $36 \%$ disapprove; $4 \%$ do not know.

From 1977 on, data come from http://webapp.icpsr.umich.edu/GSS/. The question is, "Do you agree with the following statement: A preschool child is likely to suffer if his or her mother works?" (Strongly agree $=1$, agree $=2$, disagree $=3$, strongly disagree $=4$, don't know $=8$, no answer $=9$, na $=0$.) The only modification we make is to treat "don't know" and "na" replies as missing observations. There are 14 observations: one in 1977 and then at least every 2 years from 1995 through 2004. There are between 890 and 2344 responses per year, totalling 19,005 observations. The average reply ranges from 2.2 in 1977 to 2.6 in 2004.

Merging the two data series: From the Roper data, there are three observations available before 1967 and then regular observations starting in 1970. For each of the pre-1977 observations, we compute the growth rate from one
data point to the next. Then we apply these same growth rates to project our preschool data back from 1977 to the earlier observations. We believe that using one series to infer another is a reasonably accurate procedure because for years in which both survey questions are asked, the correlation in the replies is 0.75 .

## S.1.3. Cross-Country Data

The key moments of the data that the model seeks to explain are the rise and the fall of the dispersion in female participation rates and the S-shaped increase in the level. Both of these patterns are not unique to the United States. The same patterns show up in European country data as well.

We use data from International Labor Organization (ILO), Economically Active Population, 1950-2010 (Geneva, 1997) to describe this fact. The data set covers Denmark, Finland, Sweden, the United Kingdom, Ireland, Belgium, France, Netherlands, Greece, Italy, Portugal, Spain, Austria, and Germany. We do not have local data within each country. However, we can treat each country like a region and compute the moments across countries. We computed the equally weighted mean and cross-country standard deviation of female labor force participation rates in each decade. The results are reported in Figures S. 1 and S.2.

Not only is the shape of the participation and dispersion graphs similar in Europe, the timing is similar as well. As in the United States, participation takes off in the 1970s and 1980s, and as in our model, the dispersion of participation rates peaks around 1980. The major difference is that in Europe, dispersion decreases slightly in the 1950s and 1960s, before taking off again in the 1970s.

Figure S.1.—Average female labor force participation across European countries.

FIGURE S.2.-Dispersion of female labor force participation rates across European countries.

## S.2. PANEL DATA ESTIMATION PROCEDURE

To gauge the statistical strength of the relationship between neighboring counties' LFP, we estimate the coefficients of equation (11), which we reproduce here for convenience:

$$
\begin{equation*}
\operatorname{LFP}_{i t}=\rho \operatorname{LFP}_{i(t-1)}+\beta \bar{L}_{i(t-1)}+\gamma_{t}+\phi_{i} x_{i t}+\alpha_{i}+\epsilon_{i t} \tag{S1}
\end{equation*}
$$

The term $\bar{L}_{i(t-1)}$ is the distance-weighted sum of other counties' participation rates, where the distance is 1 for counties that share a common border with the region of interest and is 0 otherwise. We construct the contiguity matrix from latitude and longitude of the centroid of each county using the function xy2cont in Pace and Barry's Spatial Statistical Toolbox for MATLAB. The spatial weight matrix is row-standardized.

The exogenous county-level control variables $x_{i t}$ are listed in Table S.III.
In the discussion that follows, we start with simple estimation procedures, point out the econometric problems that they may suffer from, and show how we address each problem. In each specification, we find that the coefficient on $\bar{L}_{i(t-1)}$, which captures the geographic relationship our model predicts, is statistically and economically significant. Furthermore, the estimates that come from the data are similar to those that emerge when we apply the same estimation procedure to the simulation output from the model. Thus, the results are consistent with the prediction of a model based on local learning.

## S.2.1. Ordinary Least Squares Estimation

The second column of Table S.III reports ordinary least squares (OLS) estimates of equation (S1). This estimation raises two causes for concern. The first issue, typical of dynamic panels, is that the lagged variable is correlated with the individual fixed effects $\left(\mu_{i}\right)$ and, therefore, with the error term. This makes the OLS estimator biased and inconsistent, even if the errors are not serially correlated. The same problem applies to the lagged spatial variable, which is a

TABLE S.III

[^0]linear combination of the $y_{i t}$ 's and, therefore, also a function of the individual effects. The second issue is that, in the presence of serial correlation in the error term, again both the lagged variable and the lagged spatial variable would be correlated with the error term. ${ }^{1}$

## S.2.2. Instrumental Variables

We first-difference (S1) to eliminate fixed effects:

$$
\begin{align*}
\mathrm{LFP}_{i t}-\mathrm{LFP}_{i(t-1)}= & \rho\left(\mathrm{LFP}_{i(t-1)}-\mathrm{LFP}_{i(t-2)}\right)+\beta\left(\bar{L}_{i(t-1)}-\bar{L}_{i(t-2)}\right)  \tag{S2}\\
& +\gamma_{t}+\phi_{i}\left(x_{i t}-x_{i(t-1)}\right)+\tilde{\epsilon}_{i t} .
\end{align*}
$$

${ }^{1}$ Static spatial panel data models have been successfully estimated using maximum likelihood (see Elhorst (2001)). This approach is not directly implementable in our context since we have an explicitly dynamic model where the lagged value of the spatial lag appears on the right hand side.

The remaining problem is that $\left(\operatorname{LFP}_{i(t-1)}-\operatorname{LFP}_{i(t-2)}\right)$ is correlated with $\tilde{\epsilon}_{i t} \equiv$ $\epsilon_{i t}-\epsilon_{i(t-1)}$. Therefore, we use $\mathrm{LFP}_{i(t-2)}$ as an instrument for $\left(\mathrm{LFP}_{i(t-1)}-\right.$ $\left.\mathrm{LFP}_{i(t-2)}\right)$. Because the spatial lag term may have similar problems, we use $\bar{L}_{i(t-2)}$ as an instrument for $\bar{L}_{i(t-1)}-\bar{L}_{i(t-2)}$.

Also, since U.S. counties may differ not just because of individual fixed effects in the levels, but also in the growth rates, in the third column of Table S.III we report estimates of equation (S2) with fixed effects. This specification is controls for time effects, individual fixed effects in levels, and individual fixed effects in growth rates while instrumenting differences with lagged levels, and still finds that the lagged labor force participation of contiguous counties is an important determinant of a county's female labor force participation rate.

As long as the errors $\epsilon_{i t}$ are serially uncorrelated, our instruments are valid. The drawback of this approach is that it is not efficient because it does not take into account all the possible moment restrictions. The next procedure remedies this problem.

## S.2.3. Arellano and Bond Estimator

Arellano and Bond (1991) pointed out that all of the lags of the dependent variable are valid instruments, as are the additional independent explanatory variables. Including these variables as instruments improves efficiency, as long as they are correlated with the regressor they are instrumenting for.

Therefore, we use three lags: $\mathrm{LFP}_{i(t-2)}, \mathrm{LFP}_{i(t-3)}$, and $\mathrm{LFP}_{i(t-4)}$, as instruments for $\left(\mathrm{LFP}_{i(t-1)}-\mathrm{LFP}_{i(t-2)}\right)$, and use $\bar{L}_{i(t-2)}, \bar{L}_{i(t-3)}$, and $\bar{L}_{i(t-4)}$ as instruments for $\bar{L}_{i(t-1)}$. In addition, we use the entire time series of all the exogenous regressors $x_{i t}$.

The results are reported in the last two columns of Table S.III. These are twostep estimates with heteroskedasticity consistent standard errors. While the estimates in the last column uses three lags as instruments for the dependent variable, the specification reported in the previous column uses only two lags and finds similar results. In both cases, the geographic variable is statistically and economically significant.

Whereas the previous IV approach was just identified, this system has more instruments than regressors and is, therefore, overidentified. Therefore, we can use the Sargan statistic to test the validity of the overidentifying restrictions and the validity of our instruments. The null hypothesis is that the instruments are not correlated with the residuals. For the model estimated in the fourth column, we obtain a $\chi^{2}(3)=1.94$ and the null hypothesis cannot be rejected with a $p$-value of 0.58 . The results of the Sargan test for the last specification are similar and indicate that the model is correctly specified.

The GMM estimator is consistent if there is no second order serial correlation in the error term of the first-differenced equation. The test statistic $m_{2}$ is the Arellano-Bond test for second order serial correlation in the errors: the null hypothesis is that of no second order serial correlation which cannot be rejected by the data ( $p$-values given in parentheses).
